Introduction

Fish escapement is the number of adults that survive juvenile and adult rearing, escape harvest and return to their natal habitat to potentially spawn (e.g. Bue et al. (1998)). For anadromous fishes, escapement is often estimated at a fixed location in a river system prior to fish reaching their spawning area. Escapement estimates facilitate effective fisheries management, and particularly, estimates of escapement for each component group (e.g., stock, population, age, origin [wild, hatchery]; Hess et al. (2014); Steinhorst et al. (2017)) provide valuable information that fisheries managers use to 27 achieve sustainable harvest, while protecting small and vulnerable populations. Accurate escapement estimates are increasingly important for depleted populations as they inform status metrics 29 (McElhany et al. 2000), and facilitate assessments of population viability and extinction risk (Ford 30 et al. 2015; Williams et al. 2016) and climate change vulnerability (Crozier et al. 2019). 31 Populations of Chinook Salmon, Oncorhynchus tshawytscha, and steelhead trout, O. mykiss, in the Snake River basin of Pacific Northwest, USA, are depleted following decades of substantial harvest and anthropogenic changes to their migration corridor (e.g., construction of hydroelectric dams on the Snake and Columbia rivers) and tributary habitats (Nehlsen et al. 1991; McClure et al. 2003; Ford et al. 2015). As a result, Snake River spring-summer run Chinook Salmon (hereafter Chinook Salmon) were classified as threatened in 1992 under the Endangered Species Act (ESA; Federal Registry Notice 57 FR 14653), and Snake River summer-run steelhead trout (hereafter steelhead) were listed as threatened five years later (Federal Registry Notice 62 FR 43937). Snake River Chinook Salmon and steelhead have substantial cultural, recreational, commercial and subsistence

value both within the Snake River basin as well as in downstream corridors (i.e., Columbia River)
and ocean fisheries. The aggregate escapement of Snake River Chinook Salmon and steelhead
populations, with the exception of Tucannon River, is monitored at Lower Granite Dam located
in southeast Washington; the final dam on the Snake River that returning adults must pass prior
to heading to tributary spawning locations. Many fisheries management and conservation actions
are made based on estimates of escapement at Lower Granite Dam parsed by species and origin
(cite BiOp, NPCC FWP, and status assessment). Additionally, harvest openings and closures,
both upstream in Snake River fisheries and downstream in mainstem Snake and Columbia River
fisheries, are predicated on escapements at Lower Granite Dam.

Chinook Salmon and steelhead returning to a majority of populations in the Snake River must ascend a fish ladder on Lower Granite Dam before migrating to their natal tributary spawning locations. Fish management agencies previously used counts of fish, by species, passing an observation window within the fish ladder as a census of fish escaping past the dam. For both species, total escapement was then parsed into groups (e.g., wild, hatchery) using observed marks and genetic data from a sample of fish captured at an adult trap located on the fish ladder upstream of the observation window (Camacho et al. 2017; Steinhorst et al. 2017). Window counts as a census proved beneficial as being an easy, straight-forward method that was ascertained in near real-time. Moreover, downriver fisheries management arenas have used window counts at lower-river dams as escapement estimates for the past several years, and consistency in methods is often desirable for management decision making (citation?).

Using window counts, however, as a census of Chinook Salmon and steelhead passing Lower
Granite Dam can be problematic as it avoids multiple sources of uncertainty and ignores known
biological processes. First, live (i.e., in-person) window counts only occur from April through
October each year. Additionally, live window counts only occur for 16-hours each day, and fish
counters working at the observation window look directly into the fish ladders to identify and count
all passing fish, by species, for only 50 minutes of each hour. Counts are then expanded to provide
an estimate for the hour (USACE 2015). From November through March, the remainder of the

year, video tape fish counting is used and only occurs for 10 hours each day; fish counters then read the video tapes and submit daily fish counts (Hatch et al. 1994). Typically, the observational error rates of live and video window counts are unknown, and sampling error rates are ignored. Additionally, two biological processes are unaccounted for: 1) fish that cross the dam during the 71 8-hours when the window is closed for counting (i.e., nighttime passage) which may result in an 72 underestimate of escapement, and 2) fish that migrate through the ladder and past the dam may 73 fallback over the dam (e.g., over spillway, through navigation locks), and later, may or may not re-ascend the fish ladder again (Boggs et al. 2004). Both fallback with no re-ascension and fallback 75 with re-ascension potentially result in an overestimate of escapement (Dauble and Mueller 2000). Previously, it was assumed that nighttime passage rates and fallback/re-ascension rates cancelled each other out resulting in window counts providing an unbiased estimate of escapement (citation?) In this study, we describe a novel method to estimate aggregate and group escapement which incorporates all sources of known uncertainty, we demonstrate the estimation method is essentially unbiased, thus better informing conservation and management decision making, and show night-time passage and fallback/re-ascension rates are unequal. Our method for estimating escapement, by species, past Lower Granite Dam incorporates window counts, data from the adult fish trap, and observations of PIT tagged fish in the adult ladder to explicitly model nighttime passage, re-ascension, and error from both window and trap estimates using a state-space approach 85 (Royle and Dorazio 2008). To meet desired management and conservation objectives, modeled escapement includes estimates of uncertainty and is parsed into weekly strata. Further, total and 87 weekly estimates are parsed into three origin groups: wild, hatchery, and hatchery no-clip. Estimates of escapement account for fish that migrate through the ladder at night outside of observation hours and account for fish that may ascend the ladder multiple times due to fallback and re-ascension. Our model is implemented in the STate-space Adult Dam Escapement Model (STA-91 DEM) package for the statistical software R (R Core Team 2020), and is available for downloaded at https://github.com/KevinSee/STADEM. To validate the STADEM results, we simulated 12 scenarios with varying trapping rates, fallback and re-ascension rates, nighttime passage rates, and window count error rates. The STADEM model combines multiple imperfect sources of data to reduce bias in escapement estimates and provide more reasonable estimates of uncertainty.

7 Methods

98 Data Requirements

We used STADEM and three sources of data to estimate Chinook Salmon and steelhead escapement at Lower Granite Dam from 2010-2019. Data sources included 1) counts of fish migrating past the observation window located on the adult fish ladder at Lower Granite, 2) information from adults captured at a fish trap located in the fish ladder, and 3) observations of previously PIT tagged fish detected in the adult fish ladder. Below, we describe each of the data sources in more detail as they pertain to Lower Granite Dam; knowing, similar data could likely be obtained from other fish passage facilities.

106 Window Counts

Daily counts of adult Chinook Salmon and steelhead passing an observation window located on 107 the Lower Granite fish ladder were the first source of data. Daily counts were made and provided 108 by the US Army Corps of Engineers, and when summed, provide an estimate of the number of 109 fish ascending and passing (i.e., escapement) Lower Granite Dam each season. Window counts 110 were made for each species using video monitoring and direct in-person visual monitoring during 111 daytime hours (Hatch et al. 1994). Video monitoring occurred during the beginning and tail ends of 112 the adult runs (March 1 – March 31 and November 1 – December) for 10 hours per day (0600 – 1600 113 hours). Direct visual monitoring occurred during peak run times (April 1 – October 31) for 16 hours 114 per day (0400 – 2000 hours) (USACE 2015). During direct visual monitoring, observers recorded 115 each adult (≥ 30cm), by species, passing the window for 50 minutes of each hour of operation. 116 Salmonids under 30cm in length were not identified to species. The sum of the daily 50-minute

counts were then multiplied by 1.2 to account for the 10 minutes when fish were not counted.

Daytime window counts were not expanded for fish that may have ascended the ladder outside
of operational hours (i.e., nighttime) (USACE 2015). Window counts were accessed through the
Columbia Basin Research Data Access in Real Time (DART) website, www.cbr.washington.edu/
dart/query/adult_daily, using their window count query. Counts were provided for each day the fish
ladder was open to passage. Although window counts were assumed to be a census of every fish
passing Lower Granite Dam, corrections were not applied for nighttime passage or re-ascending
fish. Further, there was no estimation of daily or seasonal observation or sampling error.

126 Adult Fish Trap Data

The second source of data came from a sample of fish collected in the adult trap as they migrated 127 past Lower Granite Dam (Ogden 2016a). The trap, also located within the adult fish ladder and 128 upstream of the observation window, provided biological data (e.g., origin [wild, hatchery], ge-129 netic stock, length, age, sex) for captured adults that allowed decomposition of the escapement into 130 specific groups (e.g., Camacho et al. (2019), Steinhorst et al. (2017)). The trap was operational for 131 24 hours per day, and randomly sampled the daily run by opening four times per hour for a length 132 of time determined by a set daily trapping rate. The trap rate was determined by a committee of 133 collaborating management agencies with a goal of capturing a target number of wild fish, but also 134 balancing fish handling concerns. Trap sample rates were typically 10-25%, but fluctuated through-135 out the season due to high water temperatures, decreased flows, trap malfunctions and/or closures, 136 fish handling logistics, etc. All captured fish were anesthetized, identified to species, examined for 137 existing marks/tags, and measured for fork length. Additionally, each fish had scale and genetic 138 tissue samples taken; scale samples were used to estimate age (Wright et al. 2015), tissue sam-139 ples were used to determine sex and for genetic stock identification analysis (e.g., Hargrove et al. 140 (2019)). Prior to release, all non-PIT tagged fish with an intact adipose fin (i.e., putatively wild) re-141 ceived a PIT tag. Final determination of wild, hatchery, and hatchery no-clip origins were assigned 142 using a post-hoc analysis of marks, tags, and genetic information. Data from the adult trap were

collected and managed by multiple agencies and were made available by the Idaho Department of Fish and Game (Camacho et al. 2019).

46 PIT tag Data

The last source of data was observations of PIT tagged adult Chinook Salmon and steelhead at 147 detection sites located in the Lower Granite Dam fish ladder. These observations provide estimates 148 of 1) a trapping rate, 2) the proportion of fish passing during nighttime hours (i.e., outside of window 149 observation hours), and 3) the proportion of fish that ascend the fish ladder multiple times (i.e., re-150 ascension rate). Detections used in the model include all fish that were previously PIT tagged as 151 juveniles or adults prior to reaching Lower Granite Dam (i.e., does not include newly tagged adults 152 at the dam) and detected at adult detection sites in the dam passage system. PIT tag data was 153 provided through DART and the adult ladder PIT tag query; http://www.cbr.washington.edu/dart/ 154 query/pitadult obsyr detail. 155

A trap rate estimate was derived using mark-recapture methods and PIT tag observations of both
Chinook Salmon and steelhead at Lower Granite Dam adult detection sites. The "mark" group
included all tags detected in the adult trap and the "capture" group included tags observed to cross
the weir at the upstream end of the fish ladder as adults left the passage system. Using a markrecapture model with differing capture probabilities, we estimated the trap rate on a weekly basis.
Those estimates, with associated uncertainties, were then incorporated into the model as informed
priors, while the model estimated the true trap rate based on all the data, including trap and window
counts.

The nighttime passage rate was estimated as the count of tags that migrated through the fish ladder during non-window observation hours divided by the total number of tags passing the fish ladder, and was calculated on a weekly basis. The re-ascension rate was the count of tags observed passing the upstream most detection sites in the adult fish ladder (i.e., passing the dam) and later detected re-entering the downstream end of the fish ladder at a later time divided by the total number of tags

leaving the fish ladder. Previously, we looked for differences in nighttime passage and re-ascension rates estimated using wild fish only, versus combining hatchery and wild fish together, and found no difference. Therefore, we combine wild and hatchery PIT tagged fish observations to estimate common nighttime passage and re-ascension rates to increase sample sizes.

73 Model Framework

We estimated the total number of fish crossing the dam each week, based on the window counts and 174 the total fish passing the adult trap, while also accounting for nighttime passage, and fallback/re-175 ascension rates using a state-space modeling approach (Royle and Dorazio 2008) implemented in 176 the STADEM package for the R statistical software (R Core Team 2020). We assumed that the 177 window counts and the estimates from the trap (fish in the trap divided by trap rate that week) were 178 generated by processes with observation error. In the case of the trap for example, we assumed 179 there was sampling variation and uncertainty around our estimates of the true unknown trap rate. 180 STADEM further accounted for the proportion of fish that ascended the ladder while the counting window was closed (i.e., night), as well as for fish potentially double-counted (or more) after falling back below the dam and later re-ascending the fish ladder. Finally, adult sampling data from 183 the trap (wild, hatchery, hatchery no-clip) were used to partition the total escapement estimate by 184 origin (Figure 1). Additional model details can be found in Appendix A. The STADEM package is 185 available from the primary author at https://github.com/KevinSee/STADEM, and requires the use 186 of the JAGS software (Plummer 2019) for Bayesian inference. 187

188 Simulations

We tested the STADEM model on a variety of simulated data sets. These simulated data sets contained a fixed number of unique adult fish of known origin crossing a dam, from a total of 25 fictional populations with differential run-timing (i.e., date of passage at Lower Granite Dam). Each simulated fish was given a date of ladder ascension, based on its population and the range

of run timing for that population. Each fish was also simulated to cross the dam either while the window was open for counting, or not, and was given the chance to be "caught" in the simulated fish trap given the week when it ascended the dam, and the known trap rate that week. Fallback and re-ascension behavior was also simulated, with each fish having the possibility of falling back and re-ascending the ladder up to three times.

Our objective was to examine STADEM model estimates of origin-specific (wild, hatchery, hatchery no-clip) escapement from the combinations of two separate trapping rates, two fallback/reascension and nighttime passage combinations, and three window count error rates; resulting in
twelve different scenarios (Table 1). The simulation parameters such as proportion of origin, runtiming, nighttime passage rates, fallback and re-ascension rates and trap rates were based on observed values at Lower Granite Dam between 2010-2015. Further details about simulation procedures can be found in Appendix B.

Lower Granite Application

Finally, we applied STADEM to data from Lower Granite Dam for Chinook Salmon and steelhead 206 returning to the Snake River to spawn for the spawn years 2010 to 2019. Window counts for both 207 species were accessed from DART via functions within STADEM. For Chinook Salmon, a spawn 208 year refers to adults that migrate past the dam prior to August 17 each year and spawn that late 200 summer and fall. For steelhead, the spawn year is defined as steelhead that migrate past Lower 210 Granite Dam starting July 1 the previous year and prior to June 30 of the given year (e.g., spawn 211 year 2017 steelhead migrate past Lower Granite between July 1, 2016 and June 30, 2017). Data 212 from the adult trap was made available by Idaho Department of Fish and Game, and adult PIT tag 213 detection data within the fish passage ladder at Lower Granite Dam was accessed from the PTAGIS 214 regional database (https://www.ptagis.org/).

Results

217 Simulations

Simulation results of observed bias, sampling variation, precision, root mean squared deviation 218 (RMSD), and coverage probabilities were qualitatively similar for the hatchery (N = 70,000) and 219 hatchery no-clip (N = 5,000) origin groups as observed in the wild origin group (N = 25,000) 220 comparisons. As such, only diagnostic measures of Lower Granite Dam model fits to a medium 221 sized escapement level (e.g., wild origin escapement) are presented. 222 STADEM results were very similar across all scenarios (Figure 2). Estimates were unbiased, with 223 an average relative bias of 0.2–0.3%. The CV of the estimates averaged 2.0–3.0%, with coverage 224 probabilities that always exceeded 95%. We calculated RMSD as the square root of the sum of the 225 variance of the estimate and the squared expected bias, which accounts for the size of the uncertainty 226 in the estimator as well as its bias. The RMSD was near 500 for each scenario, representing an 227 estimate within 2% of the true value (Table 2). 228

Lower Granite Application

We applied STADEM to data from Lower Granite Dam for Chinook Salmon and steelhead for spawn years 2010–2019. Estimates of total escapement, as well as estimates of wild, hatchery, and hatchery no-clip estimates are presented in Table 3. Coefficients of variation ranged from 2.7-233 24.8% for wild fish, 2.2-10.5% for hatchery fish, 3.6-11% for hatchery no-clip fish and 2.1-10.4% for total unique fish past Lower Granite Dam.

Weekly estimates of total escapement over Lower Granite Dam tracked the window counts and trap

Weekly estimates of total escapement over Lower Granite Dam tracked the window counts and trap
estimates (Figure 3). STADEM point estimates were often between estimates based on window
counts, and those based on the number of fish caught in the adult trap. However, when very few
fish were caught in the trap, or there was more uncertainty about the trap rate that week, STADEM

estimates tracked the window counts more closely, as seen in the second week of July 2014, in Figure 3. That year also shows the utility of STADEM in dealing with missing data, as the trap was shut down for several weeks in July and August.

Examining the estimates of nighttime passage and re-ascension rates based on the observed PIT tags crossing over Lower Granite Dam, the two rates did not match up (Figure 4). In particular, there are several weeks when the window counts are quite high, and the rates differ by as much as 10%. Clearly, those two biological processes do not cancel each other out, and thus, employing a model that accounts for both will result in more accurate estimates of escapement.

Discussion

We have presented a novel method for estimating adult salmonid escapement past a large hydroelectric facility (e.g., Lower Granite Dam) that incorporates data from window counts, fish trap, 249 and observations of PIT tagged fish in the adult passage ladder. Our model explicitly models night-250 time passage, re-ascension, and potential error in both window and trap estimates. In doing so, we 251 demonstrated that at Lower Granite Dam, nighttime passage and re-ascension rates do not always 252 offset each other, and assuming they do will lead to biased escapement estimates in some years. 253 With minor adjustments this modelling framework and the STADEM package could be applied 254 to similar migratory species at Lower Granite Dam (e.g., fall Chinook Salmon, Pacific lamprey, 255 Lampetra tridentata), or elsewhere; provided a fish passage barrier with a counting mechanism, a 256 trap that can be used to sample a portion of the run, and a tag observation or detection infrastruc-257 ture (e.g., a PIT tag detection array or similar) exists. Our state-space model combined multiple 258 imperfect sources of data to reduce bias in adult escapement estimates and provided more reason-259 able estimates of uncertainty. Accurate population or stock abundance estimates and uncertainty 260 accounting for observation and process error can be particularly important when estimates are used or leveraged for management and conservation decisions such as population viability analyses.

Combining data from the adult fish trap with live and video window counts provides several bene-

fits. First, it allows us to model observer error in the window counts, which is typically unknown. If estimates rely on window counts alone, quantifying observer error is impossible, and we believe it's prudent to capture and account for known sources of error to minimize management decision risk. Second, by incorporating both sources of information in a state-space framework, STADEM 267 incorporates missing data at either the observation window or adult trap seamlessly. At Lower 268 Granite Dam, the adult trap has been closed for brief or extended periods of time (i.e., days, weeks) 269 intermittently over the past several years, often during peak run times. Trap closures are typi-270 cally associated with elevated water temperatures resulting in potential fish handling stress and/or 271 trap malfunctions. Given predicted Pacific Northwest climate change scenarios trap closures from 272 high water temperatures may become more commonplace in the future; amplifying the need for a 273 modeling framework that accounts for periods of missing data while still capturing estimate uncer-274 tainty. Additionally, having a framework in place that accounts for missing periods of data will 275 allow for increased logistic flexibility if, for example, maintenance or construction is needed at the 276 observational window or adult trap. 277

Although not currently set up for this, STADEM could be modified and run on a weekly basis or in near real-time to provide better in-season estimates for fisheries managers. Currently, the only roadblock to this, at Lower Granite Dam, is the identification of hatchery origin fish from 280 phenotypically wild fish (i.e., hatchery no-clip) using genetic tissues samples (Steele et al. 2013) 281 collected at the adult trap, which currently is completed post-hoc after the trapping season. The 282 inclusion of genetic information typically results in a reduction in wild escapement estimates and an 283 associated increase in hatchery no-clip escapement. However, if in-season management decisions 284 do not require this correction or could accept the potential bias, origin calls at the trap could be 285 used in-season as a first approximation to escapement. Final post-hoc estimates, parsed by origin, 286 could then be finalized at season's end. All other data included in this model (e.g., window counts 287 and PIT observations) are otherwise provided in almost real-time by DART. Provided the Lower 288 Granite Dam adult fish trap database was updated and made available frequently, there are minimal 289 obstacles for adapting the STADEM framework to provide in-season estimates of escapement.

Recently, co-managers in the Snake River basin have adopted the STADEM framework to estimate population escapement of spring/summer Chinook Salmon and steelhead past Lower Granite Dam, 292 and returning to tributary or population specific spawning areas (Kinzer et al. 2020a, 2020b). Es-293 timates of escapement at Lower Granite Dam, by species and origin, including known uncertainty, 294 are available to further parse into sex- or age-structured escapement estimates (e.g., Camacho et 295 al. (2017), Schrader et al. (2013)) that are important for fisheries management and productivity 296 monitoring of wild populations. As an example, STADEM is being applied at Lower Granite to 297 estimate the total unique wild fish migrating past the dam. Estimates of fish passing the dam are 298 then combined with estimated movement or transition probabilities based on PIT tag observations 299 at instream PIT tag detection systems throughout the Snake River basin, similar to Waterhouse et 300 al. (2020), to estimate escapement to Snake River populations and locations throughout the basin 301 (Orme et al. 2018). Combined, escapement estimates from STADEM and movement probabil-302 ity estimates provide abundance estimates to given tributaries or populations that, joined with sex 303 and age data collected at the adult fish trap (Hargrove et al. 2019), provides necessary informa-304 tion to evaluate productivity and population viability for select Snake River Chinook Salmon and 305 steelhead groups (Kinzer et al. 2020b). Although STADEM was developed with salmonid escapement at Lower Granite Dam in mind, it 307 could be applied to any migratory fish species at locations with similar monitoring infrastructure. 308 Justification and infrastructure exist for applying a modified STADEM framework for fish pass-300 ing Bonneville Dam, the lowest dam on the Columbia River, or Priest Rapids Dam in the upper 310 Columbia River. Both locations currently trap a sub-sample of passing Chinook Salmon and/or 311 steelhead for biological information, and use window counts as a surrogate of true escapement. 312 However, each has at least some similar problems to those observed at Lower Granite Dam, such 313 as unaccounted observer and sampling error, night-time passage, and/or re-ascension. Certainly, 314

estimating an unbiased total return to the entire Columbia River basin (i.e., Bonneville Dam) and

Upper Columbia River with uncertainty would benefit managers and decision making.

315

317 Acknowledgements

Funding for this study and development of the STADEM model was partially provided by the Bon-318 neville Power Administration under project 2003-017-00. Special thanks to Darren Ogden and staff 319 at the Lower Granite Dam adult trap for their hard work and diligent data collection. Thank you 320 to personnel at the Idaho Department of Fish and Game, particularly Paul Bunn, Tim Copeland, 321 and Bill Schrader, for providing access to data from the adult fish trap and conceptualizing meth-322 ods, and the staff at the Eagle Fish Lab for analyzing genetic samples. Special thanks to Columbia 323 Basin Research staff and the Columbia River Data Access in Real Time (DART) application, and 324 Susannah Iltis in particular. And finally, thank you to Rick Orme for his contributions to the de-325 velopment of STADEM, and all the other folks who have contributed through productive critique and conversations.

Steelhead	2019	51,818	56,024 (0.104)	11,073 (0.248)	41,726 (0.079)	3,224 (0.092)

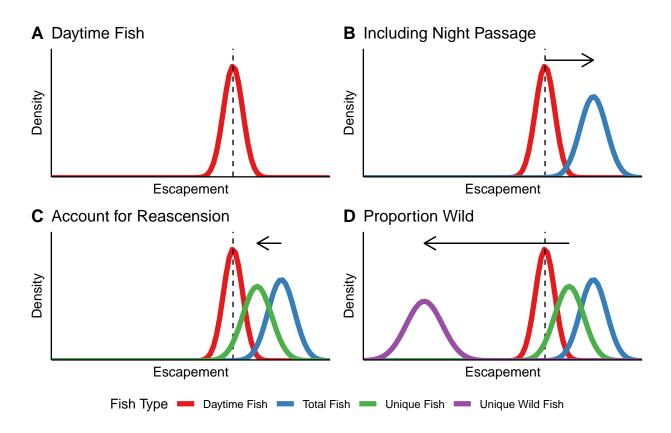

Figure 1: Schematic of how the STADEM model works. Panel A shows the posterior of the estimate of fish crossing the dam while the window is open (dashed line shows observed window counts). That estimate is divided by the nighttime passage rate (B). The total fish is then discounted by the reascension rate to estimate unique fish (C). Those unique fish are then multiplied by the proportion of wild fish (D), to estimate unique wild fish.

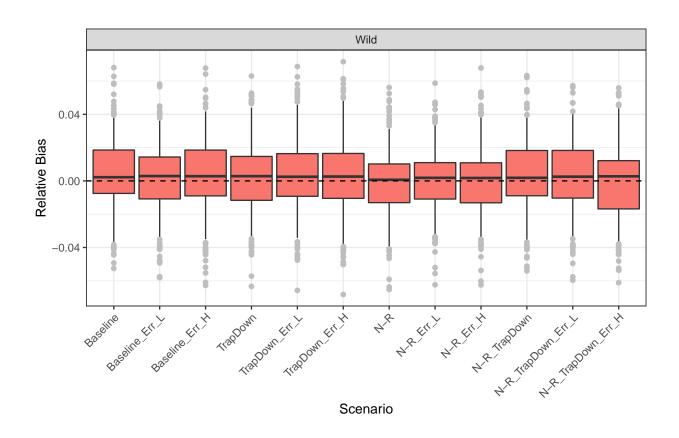

Figure 2: 'Boxplots show relative bias of STADEM estimates for wild escapement across various scenarios. The boxes contain 50% of the simulations, whiskers contain 95% of the simulations, and points are outliers.

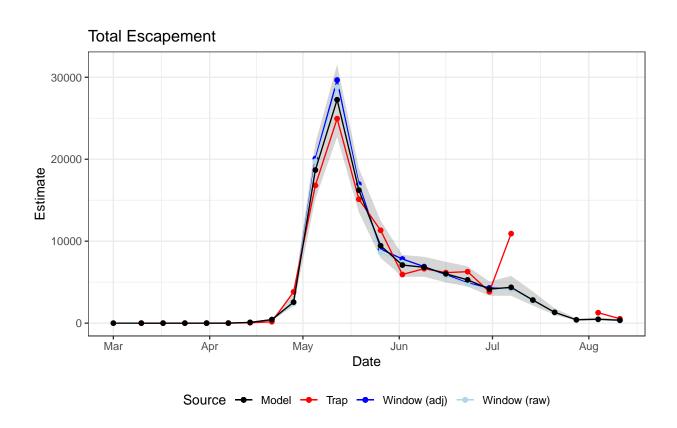

Figure 3: Time-series plot showing estimates of total escapement for Chinook in 2014, including raw window counts, window counts adjusted for night-time passage, trap estimates and STADEM estimates. Gray ribbon represents the 95% credible interval for STADEM estimates.

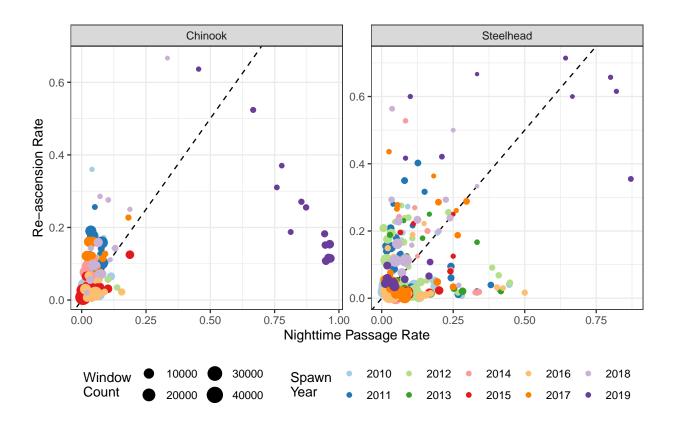

Figure 4: Night-time passage rate plotted against re-ascension rate, calculated from observed PIT tags for each week of spawn years 2010-2019. Colors correspond to different spawn year, while the size of each point is proportional to the window count that week. The dashed line is the 1-1 line.

Appendix A - STADEM Model Description

Total and Weekly Escapement

Escapement at Lower Granite Dam (LGD) is estimated by combining two independent observations, trap catches and window counts, of the true number of fish crossing the dam in a state-space model (Royle and Dorazio 2008) with a weekly time-step. Both are assumed to be corrupted observations of the true unknown number of fish crossing LGD each week. The log of the true number of fish crossing (X_t), is modeled as a random walk process (Shumway and Stoffer 2010).

$$\ln \left(X_{t} \right) = \ln \left(X_{t-1} \right) + e_{t}$$

$$e_{t} \sim \mathcal{N}(0, \sigma_{X}^{2})$$

The number of fish caught in the trap, Y_t^T , for week t is modeled as a binomial process based on the unknown true trap rate that week, ν_t , and the unknown true number of fish crossing the dam that week, X_t . The true trap rate is estimated from a beta distribution with previously estimated parameters, $\hat{\alpha_t}$ and $\hat{\beta_t}$, informed by the mark-recapture estimate of the trap rate.

$$u_t \sim \operatorname{Beta}\left(\hat{\alpha_t}, \hat{\beta_t}\right)$$

$$Y_t^T \sim \operatorname{Bin}\left(\nu_t, X_t\right)$$

The estimate of the weekly trap rate is derived based on previously PIT-tagged spring/summer Chinook and steelhead who are crossing LGD that week. The fish caught in the trap that week are considered the "mark" group, and all the PIT tagged fish who are detected at the upper end of the LGD fish ladder that week are considered the second capture group (which includes recaptures of the the "marked" fish). From this data, we can estimate the total number of previously PIT tagged fish crossing LGD that week, and the proportion of those that are caught in the trap is the weekly trap rate. The uncertainty in estimates of total fish is translated into uncertainty in the trap rate, and this is then summarised with a beta distribution (Beta $(\hat{\alpha}_t, \hat{\beta}_t)$) that becomes an input into

STADEM. Although the group of previously PIT tagged fish is not assumed to be representative of the overall run, the rate at which they are caught in the trap should be the same rate that the overall run experiences.

The number of fish counted at the window, Y_t^W , is modeled as a (potentially) over-dispersed negative binomial process, with an expected value of X_t^{day} , the number of fish crossing the dam while the window is open. This is simply the total number of fish crossing that week, X_t , multiplied by the proportion of fish crossing while the window is open for counting, θ_t , calculated on a weekly basis. In the formula below, p_t is the proportion of fish observed at the window and r is the shape parameter. If r is estimated to be small it provides evidence for over-dispersion, and as it grows very large, the negative binomial distribution behaves like a Poisson distribution.

$$\begin{split} X_t^{day} &= X_t * \theta_t \\ p_t &= \frac{r}{\left(r + X_t^{day}\right)} \\ Y_t^W &\sim \text{NegBin}\left(p_t, r\right) \end{split}$$

Thus, the unknown true number of fish crossing LGD each week, X_t , is estimated from two different data source: window counts and fish sampled in the trap. The window counts provide an 441 estimate (with some potential observer error) of the fish crossing during daytime hours, while the fish in the trap, when expanded by the estimated true trap rate, provide an estimate of the total fish crossing that week. For weeks when we have a more precise estimate of the trap rate (i.e. weeks when lots of previously PIT tagged fish are crossing LGD), STADEM will tend to favor the estimate 445 of total escapement based on the trap data, whereas when that trap rate is more uncertain (e.g. fewer 446 PIT tagged fish to use in estimating the trap rate), STADEM will rely more on the window counts 447 to estimate total escapement. During peak run times, when lots of fish are crossing LGD, estimates 448 based on trap data and trap rates will be more precise, while estimates from the window counts may 449 have more observation error due to so many fish passing the window. For weeks when the trap is 450 down, STADEM relies exclusively on the window counts and night-time passage data, but there 451

will be more uncertainty in the estimates.

(Shumway and Stoffer 2010).

464

Day-time Passage and Re-ascension Rates

There are two other processes that must be accounted for, first, the proportion of fish that cross the 454 dam while the window is closed for counting (night-time passage rate), and the second, the propor-455 tion of fish that are crossing the dam multiple times (re-ascension rate) and therefore potentially 456 double-counted. Both rates can be estimated from previously PIT tagged fish that are crossing the 457 dam each week. 458 The proportion of fish passing the window during non-operational hours, night-time passage rate, 459 is just the complement of the rate of fish passing during the day when the window is operating. The 460 daytime passage rate for week t, θ_t , is modeled as a random walk process and estimated from a 461 binomial distribution based on the number of PIT tags observed to cross the dam during operational 462 hours, y_t^{day} , and the total number of PIT tags observed to cross the dam at any point that week, N_t 463

$$\begin{aligned} y_t^{day} &\sim \text{Bin}\left(\theta_t, N_t\right) \\ & \text{logit}(\theta_t) = \text{logit}\left(\theta_{t-1}\right) + g_t \\ & g_t &\sim \mathcal{N}(0, \sigma_{\theta}^2) \end{aligned}$$

The number of total fish crossing Lower Granite differs from the number of unique fish crossing Lower Granite because some fish fall back and re-ascend the dam. These fish are potentially double-counted at the window, and have the potential to be caught in the fish trap more than once. The number of tags known to be re-ascending the dam each week, y_t^{reasc} , is modeled as a binomial process based on the estimated re-ascension rate, η_t , and the total number of tags crossing the dam that week, N_t . The logit of the re-ascension rate is modeled as a random walk process similar to day-time passage (Shumway and Stoffer 2010).

$$\begin{split} y_t^{reasc} &\sim \text{Bin}\left(\eta_t, N_t\right) \\ &\text{logit}\left(\eta_t\right) = \text{logit}\left(\eta_{t-1}\right) + f_t \\ &f_t \sim \mathcal{N}(0, \sigma_\eta^2) \end{split}$$

Origin Proportions

After estimating the total number of fish to have crossed Lower Granite each week, X_t , the total 473 must be further refined into the number of wild fish, $X_{w,t}$, hatchery fish, $X_{h,t}$ and hatchery no-clip 474 fish, $X_{hnc,t}$. This is done by estimating a weekly origin proportion vector, ω_t based on the random 475 sample of fish caught in trap that week, Y_t^T . The observed number of wild, $Y_{w,t}^T$, hatchery, $Y_{h,t}^T$, and 476 hatchery no-clip, $Y_{hnc,t}^T$, fish caught in the trap that week is assumed to come from a multinomial 477 distribution with probability vector ω_t . The log-odds ratio of the proportions in ω_t , in relation to the 478 proportion of hatchery fish, $\omega_{h,t}$ is modeled as a random walk, so it can change through time. This 479 allows the proportions of wild, hatchery and hatchery no-clip fish to shift throughout the season, 480 based on the data available from the fish trap. 481

$$\begin{split} \left(Y_{w,t}^T, Y_{h,t}^T, Y_{hnc,t}^T\right) &\sim \text{Multinom}\left(\omega_t, Y_t^T\right) \\ \omega_t &= \frac{\exp(\phi_t)}{\sum \exp(\phi_t)} \\ \phi_{w,t} &= \ln\left(\frac{\omega_{w,t}}{\omega_{h,t}}\right) \\ \phi_{hnc,t} &= \ln\left(\frac{\omega_{hnc,t}}{\omega_{h,t}}\right) \\ \phi_{h,t} &= 0 \\ \phi_{w,t} &= \phi_{w,t-1} + d_{w,t} \\ \phi_{hnc,t} &= \phi_{hnc,t-1} + d_{hnc,t} \\ d_t &\sim \mathcal{N}(0, \sigma_\omega^2) \end{split}$$

Finally, the number of unique fish crossing Lower Granite each week, $X_{w,t}$, is the product of the

total fish crossing that week, X_t multiplied by one minus the re-ascension rate, $(1-\eta_t)$, and the origin proportion vector, ω_t .

$$\begin{bmatrix} X_{w,t} \\ X_{h,t} \\ X_{hnc,t} \end{bmatrix} = X_t * (1 - \eta_t) * \begin{bmatrix} \omega_{w,t} \\ \omega_{h,t} \\ \omega_{hnc,t} \end{bmatrix}$$

485 Model Fitting

The model was fit using the JAGS program (Plummer 2019), run with R software (R Core Team 2020). Uninformative priors were used for $\sigma_X, \sigma_\eta, \sigma_\theta, \sigma_\omega$ and $\ln(X_1)$ (Uniform(0,10)), as well as logit(η_1) and logit(θ_1) ($\mathcal{N}(0,1000)$), and finally $\phi_{w,1}$ and $\phi_{hnc,1}$ ($\mathcal{N}(0,100)$).

Appendix B - Simulation Details

To simulate fish passing a dam, an \mathbb{R} software function was developed (R Core Team 2020). The function randomly samples observations from assumed probability distribution functions (\mathcal{PDF}) with known parameters. Total unique fish, N, and a vector, ω , containing the proportions of wild (w), hatchery (h) and hatchery no-clip (hnc) fish passing the dam is set to establish known "truths" of escapement by origin.

$$[N_w,N_h,N_{hnc}]=N*[\omega_w,\omega_h,\omega_{hnc}]$$

Escapement is then randomly divided across a set number of populations, n, by randomly drawing proportions, $\phi_{j,p}$, of origin group j in each population p using a dirichlet \mathcal{PDF} . The dirichlet function is parameterized from a vector, η_j , containing 1's and 0's designating populations with origin j fish returning. η_j originates from a bernoulli \mathcal{PDF} and the proportion of populations with each origin, τ_j . Wild fish are assumed to be in all populations; $\tau_w=1.0$. The product of sampled population proportions $\phi_{j,p}$ and fixed N_j yields a random variable of abundance for each origin in each population, $N_{j,p}$. Summing across origin abundances then gives a random total population abundance, N_p , crossing the dam.

$$\begin{split} \left[\eta_{j,p=1},...,\eta_{j,p=n}\right] &\sim \text{Bern}(\tau_j) \\ \left[\phi_{j,p=1},...,\phi_{j,p=n}\right] &\sim \text{Dir}(\eta_{j,p=1},...,\eta_{j,p=n}) \\ N_{j,p} &= N_j * \phi_{j,p} \\ N_p &= \sum_{i=w,h,hnc} N_{j,p} \end{split}$$

Mean arrival date, \bar{a}_p , for each population returning to the dam is drawn from a normal \mathcal{PDF} with hyper-parameters μ_a and σ_a^2 . Similarly, the variance or spread in run-timing within populations is the absolute value of random variables drawn from a normal \mathcal{PDF} with hyper-parameters μ_s and

506 σ_s^2 .

$$\begin{split} \left[\bar{a}_p, ..., \bar{a}_n \right] &\sim \text{Norm}(\mu_a, \sigma_a^2) \\ \left[s_p, ..., s_n \right] &\sim \text{Norm}(\mu_s, \sigma_s^2) \end{split}$$

After sampling the mean date of arrival and variances for each population, the date of arrival, $a_{i,p}$, for individual fish, i, within each population are drawn from a normal \mathcal{PDF} with population parameters \bar{a}_p and s_p^2 . This simulates a random arrival day that is similar for all fish returning to the same population, regardless of origin.

$$date_{i,p} \sim \text{Norm}(\bar{a}_p, s_p^2)$$

To examine the sensitivites of models to different fish behavior and dam operational scenarios, 511 seven additional attributes are randomly assigned to each individual fish. Each attribute is randomly 512 assigned a TRUE/FALSE using a bernoulli \mathcal{PDF} and a fixed probability parameter. Fish passage during the day-time (i.e., during periods of window operation) is modeled using one minus the night-time passage rate $(1 - \nu)$. Window observations are conditioned on fish passing during the 515 day and being observed at a set rate, γ . Whether fish i is sampled by the adult trap is modeled on 516 the weekly set trap rate, δ_t . The rate of previously PIT-tagged fish is determined by λ , and their 517 subsequent detection at the ladder PIT antenna is governed by κ . Fallback behavior is modeled with 518 a common rate across all populations, ψ . Re-ascension occurs with probability ρ , conditioned on 519 fish i falling back. If fish i falls back and re-ascends, the entire process described above is repeated, 520 with some time-lag between initial ascension and re-ascension that is governed by a Poisson \mathcal{PDF} 521 with mean = 2 days. Fish may fall-back and re-ascend up to 3 times, allowing for the possibility of 522 the same fish being counted or trapped multiple times. 523

$$\begin{aligned} day_i \sim \mathrm{Bern}(1-\nu) \\ window_{i|d=TRUE} \sim \mathrm{Bern}(\gamma) \\ trapped_i \sim \mathrm{Bern}(\delta_t) \\ tagged_i \sim \mathrm{Bern}(\lambda) \\ ladder_{i|m=TRUE} \sim \mathrm{Bern}(\kappa) \\ fallback_i \sim \mathrm{Bern}(\psi) \\ re - ascend_{i|f=TRUE} \sim \mathrm{Bern}(\rho) \end{aligned}$$

524

Simulation parameters for model evaluations were set to mimic typical ecapement of spring/summer Chinook Salmon to LGD with similar origin proportions, marking rates and 525 run timing as those observed from return years 2010 - 2015. Escapement of each origin (N_i) 526 was set at 25,000 wild, 70,000 hatchery and 5,000 hatchery no-clips spread randomly across 527 25 populations (n). Of the 25 populations, each had a 1.0 probability of containing wild fish, 528 0.50 probability of having hatchery fish and 0.15 probability of receiving hatchery no-clip (τ_i) ; 529 resulting in an expected 25 wild, 12.5 hatchery and 3.75 hatchery no-clip populations. Mean 530 arrival dates and variability were estimated from PIT-tag detection data queried from the Columbia 531 Basin Research Data Access in Real Time (DART) website and organized by release subbasin. 532 Mean arrival date across all subbasins and 2010 - 2015 return years was June $19^{th}~(\mu_a=171)$ with a standard deviation of 13 days (σ_a). While the observed spread (i.e., variance) of arrival 534 dates within subbasins was determined to have a mean (μ_s) of 22 days and a standard deviation of 535 7 days (σ_s) . 536 For the specific simulated scenarios, we were interested in STADEM model estimates of origin 537 specific escapment from the combinations of two seperate trapping rates, two fallback, re-ascension 538 and night-passage combinations and three window count error rates; resulting in twelve different 539 scenarios. First, trapping rates were set static at 0.15 across all weeks for six scenarios to mimic 540 an optimium trap operation for an expected return of 25,000 wild fish (i.e., trap $\approx 4,000$ wild fish). 541

For the remaining six scenarios, trapping rates for weeks 30, 31 and 32 (i.e., July 22^{nd} to August 11^{th}) were changed to 0.00 to test STADEM sensitivities to potential trap shut downs similar to those observed in 2013, 2014 and 2015 (Ogden 2014, 2016b, 2016a). To simulate and control the number of re-ascending and night-time passing fish to model response, we altered fallback and 545 night-time passage rates while holding the re-ascension rate constant at $\rho = 1.0$. Altering fallback 546 rates and holding re-ascension constant allowed for a more simple control of the number of fish 547 re-ascending; because the number of re-ascending fish is a function of the number of fallbacks 548 and the re-ascension rate. Six scenarios had equal rates of fallback and night-time passage set at 549 $\psi = \nu = 0.06$ (Boggs et al. 2004) which means other estimator assumptions (Schrader et al. 550 2013). The other six scenarios set fallback at $\psi=0.10$ and night-time passage at $\nu=0.05$ 551 to create a 5.0% positive bias of unique fish at the window. A potential 5.0% weekly bias was 552 determined from PIT-tag data and within the range of observed weekly difference for return years 553 2010 - 2015 (Figure 4). Finally, we desired to test the sensitivities of STADEM to potential rates 554 of window count error; 0%, 5% and 10% (Hatch et al. 1994). Error at the window was simulated 555 as unbiased (i.e., expect varying high and low counts to cancel each other) and is introduced to the 556 sum of daily window counts using a normal \mathcal{PDF} .
